Abstract

Physical task stress affects the acoustic speech wave in various ways. Motivated by observations that fundamental frequency and open quotient are affected by physical task stress, this study examines the effects of physical task stress on a set of glottal features. It is shown that a set of six glottal features can be used for physical stress detection, implying that physical task stress affects vocal fold behavior. It is also shown that the distributions of these six glottal features, across all available speech data, are not affected by physical task stress, leading to the conclusion that covariation in the features due to physical task stress represents different behavioral responses to physical stress. Age and exertion level are explored and rejected as explanatory variables for behavioral types. It is shown, however, that the glottal measurements show changes in distribution when restricted to one recording session of one speaker, suggesting that a given speaker may adopt and retain a particular response to physical task stress for the duration of a task.

Index Terms: glottal waveform, physical task stress, stress detection

1. Introduction

The inference of emotional and physical states of speakers by analysis of the speech signal is of great interest. For example, in the course of the performance of their duties, brush firefighters undergo extreme physical demands. A summary of the overall physical state of their personnel, their task demands, and fatigue levels, through analysis of a variety of physiological signals as well as the speech signal, might one day prove to be invaluable adjunct information to central staff who must decide where to spend limited human firefighting resources. Thus it is of value to catalog the effects of physical task stress on speech and to develop systems that can infer the influence of physical task stress on speakers.

The effects of physical task stress on the speech production system are often subtle. Some of them are known in the literature. Fundamental frequency (F0) increases for most speakers [1] while the variance of F0 does not increase [2]. The glottal open quotient decreases in physical task stress [3]. The center frequencies of the first two formants decrease in certain contexts [3]. There is evidence that high vowels are affected differently than low vowels [4], and that nasals are affected more than fricatives and plosives [4].

Recent advances in methods for the estimation of the glottal volume velocity waveform have added to an already large

catalog of methods for analysis of the acoustic consequences of changes in vocal fold behavior [5]. Various types of non-modal phonation are known to have a distinct effect on glottal waveform parameters, such as loud and soft speech [5], and breathy and pressed phonation types [6] [7]. Hypothetically, physical task stress could result in at times breathy and at other times pressed phonation. Given evidence that the glottal open quotient decreases due to physical task stress [3], the research question posed in this study is whether the effects of physical task stress manifest as extensive changes in glottal volume velocity waveform parameters, as observed for other speech types.

A stress detection system is first used to establish the dependence of six glottal waveform parameters on physical task stress. These six parameters are then measured and compared in physical task stress and neutral speech.

2. Corpus

The physical task stress data used in this study is drawn from the first and second physical task stress collects of the UT-Scope corpus [8] [3]. The first and second stages of the collect (in 2007 and 2010, respectively) were collected in the same sound booth, using the same recording equipment and microphone, on the same exercise machine, and both include a 35-sentence prompted speech segment in both physical stress and neutral tasks. This study uses the 35-sentence prompted segment, drawn from 70 female native speakers of American English. Some speakers spoke multiple sessions, and some utterances were repeated due to pronunciation mistakes, resulting in a total of 2815 neutral utterances and 2717 physical stress utterances. The collection paradigm subjects each participant to the same physical task, resulting in a different level of exertion across speakers, depending on their physical fitness. For most speakers, the task resulted in a medium level of exertion, one in which they could comfortably speak [4].

3. Stress detection

The purpose of the following experiment is to determine whether physical task stress affects the glottal waveshape. Systems for physical task stress detection [9] use MFCCs and TEO-CB-AutoEnv [10] as acoustic features, and a pair of GMMs as classifier. This experiment tests glottal waveshape features. The six features used are discussed in Section 4. They are mostly dependent on the glottal waveshape and thus on vocal fold behavior.

The detection task is to determine whether or not a given 2-3 second sentence was produced in the context of physical task stress. The stress detection system uses the log likelihood ratio between a pair of 512 mixture GMMs as classification statistic. Several speakers recorded two sessions and all recorded data

Table 1: Detection accuracy as a function of acoustic feature. Chance level is 50% accuracy.

System	Accuracy (%)
MFCCs	74.4
6 glottal features	69.0
Feature fusion	74.0
System fusion	74.1

was included in the evaluation task. Some speakers repeated utterances because of pronunciation mistakes, resulting in different numbers of physical task stress and neutral utterances. The training data consists of 1,695 neutral utterances, and 1,632 physical task stress utterances, from 45 speakers. The evaluation data consists of 1,085 physical task stress utterances and 1,120 neutral utterances, from 25 speakers not included in the training data. The baseline feature is 13 dimensional MFCCs with deltas and double-deltas, 25 ms frames and 10 ms frame hop.

The stress detection task here is not directly comparable to [9]. In the present study, the detection utterances have all been carefully hand-clipped to ensure that no recorded breaths are contained. This ensures that the detection task is concerned with the speech signal, rather than breaths, because the glottal parameter analysis discussed in Section 4 is concerned solely with the speech signal.

Table 1 shows the detection accuracy results for each feature set. The system using the 6 glottal features achieved a 69% detection accuracy. This suggests that physical task stress affects the glottal waveshape in detectable ways. This is not surprising, given previous analysis results [3], and given that a cognitive stress detection system using similar glottal waveshape parameters resulted in an above-chance detection accuracy [11]. However, what is surprising is that neither feature level fusion nor system level fusion with MFCCs results in an improvement over the MFCC detection accuracy. This is inconsistent with results for cognitive stress, in which a 6% absolute improvement in detection accuracy for fusion was observed [11]. Section 4 explores the effects of physical task stress on these six glottal waveshape parameters in more detail.

4. Glottal and acoustic speech waveform parameters

Section 3 showed that a set of six glottal features are dependent on physical task stress. These features are discussed in this section and are the subject of an analysis. For other types of non-neutral voicing including pressed, breathy, soft, and loud, an average across all frames of all speakers has been sufficient in the literature to demonstrate that glottal parameters are dependent on the speech type under study [7] [5]. This section demonstrates that this is not the case for physical task stress, and proceeds to explore age, exertion level, and speaker identity, in the search for a grouping of responses that might demonstrate a dependence of the parameters on physical task stress.

Three of the parameters are measured from an estimated glottal volume velocity waveform; the remaining three are measured directly from the acoustic wave. The GLOAT toolkit [5] is used to estimate the glottal volume velocity waveform derivative; an integrating filter is used to estimate the volume velocity waveform. The GLOAT toolkit is used to select only voiced frames for speech analysis, and to estimate the fundamental frequency. Analysis frames of 25 ms are used, with a fixed 10 ms frame skip.

4.1. Harmonics to Noise Ratio

The Harmonics to Noise Ratio (HNR) [12] was developed as a measure of hoarseness of a speaker. The HNR as originally defined is computed by averaging in the time domain across a window of nearby pitch periods to obtain the average periodic component, and then subtracting this average from one pitch period to obtain the noise component, and taking the ratio of the energy of the periodic component to the energy of the noise component. A cepstral method is used here to estimate the HNR [13].

4.2. F1F3syn

F1F3syn is designed to detect aspiration noise at the glottis [15]. It is computed from the cross-correlation of the low-pass filtered Hilbert envelopes of two wide frequency bands (100Hz-1.5kHz, 1.8-4kHz). If there is more aspiration noise than in typical neutral speech, the harmonic structure in the two bands will be less correlated and the F1F3syn will be lower.

4.3. Normalized Amplitude Quotient

The Normalized Amplitude Quotient (NAQ) is the ratio of the maximum amplitude of the glottal flow to the minimum of the glottal flow derivative, normalized by the fundamental period and the sampling frequency [7]. NAQ is sensitive to variations caused by breathy and pressed phonation [7] and to soft and loud speech [5]. NAQ increases for breathy phonation and decreases for pressed phonation, relative to neutral speech.

4.4. Harmonic Richness Factor

The Harmonic Richness Factor (HRF) is the ratio of the sum of the amplitudes at the harmonics in the glottal waveform to the amplitude of the component at the fundamental frequency [16]. In [16], the HRF of modal voicing was higher than that for breathy voicing by 6.8 db. In [5], there were clear shifts in the distribution of HRF between loud, modal, and soft voicing.

4.5. H1H2 Ratio

The H1H2 ratio is the ratio between the amplitude at the first harmonic to the amplitude at the second harmonic [17]. In that study, an increase in the H1H2 ratio was correlated with perceived breathiness.

4.6. Spectral Slope

The spectral slope is well known as the slope of the least-squares regression line fitted to the log-magnitude spectrum bins for one speech frame, and is measured in decibels. Angry, loud, and Lombard effect speech significantly affect the spectral slope [14]. The spectral slope for voiced frames is typically negative. If the glottal waveshape is less smooth than typical neutral speech, it will have a stronger harmonic structure, and a spectral slope closer to 0.

4.7. Global analysis

All frames of all speakers were used to create a pair of histograms for each of the six parameters, shown in Figure 1. These plots stand in sharp contrast to the results from [5], where glottal parameters from loud and soft speech were found to vary significantly from neutral when a histogram was plotted across
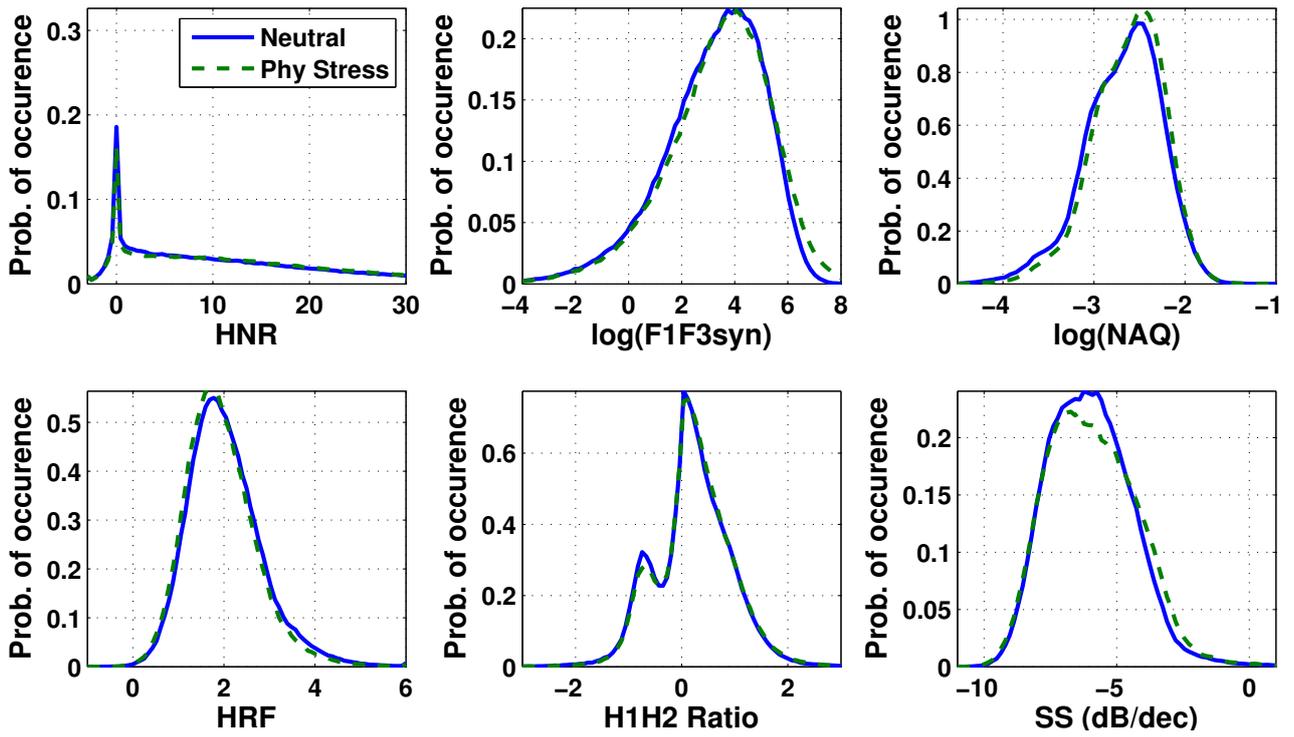

Figure 1: Parameters in physical task stress and neutral, across all voiced frames for all speakers.

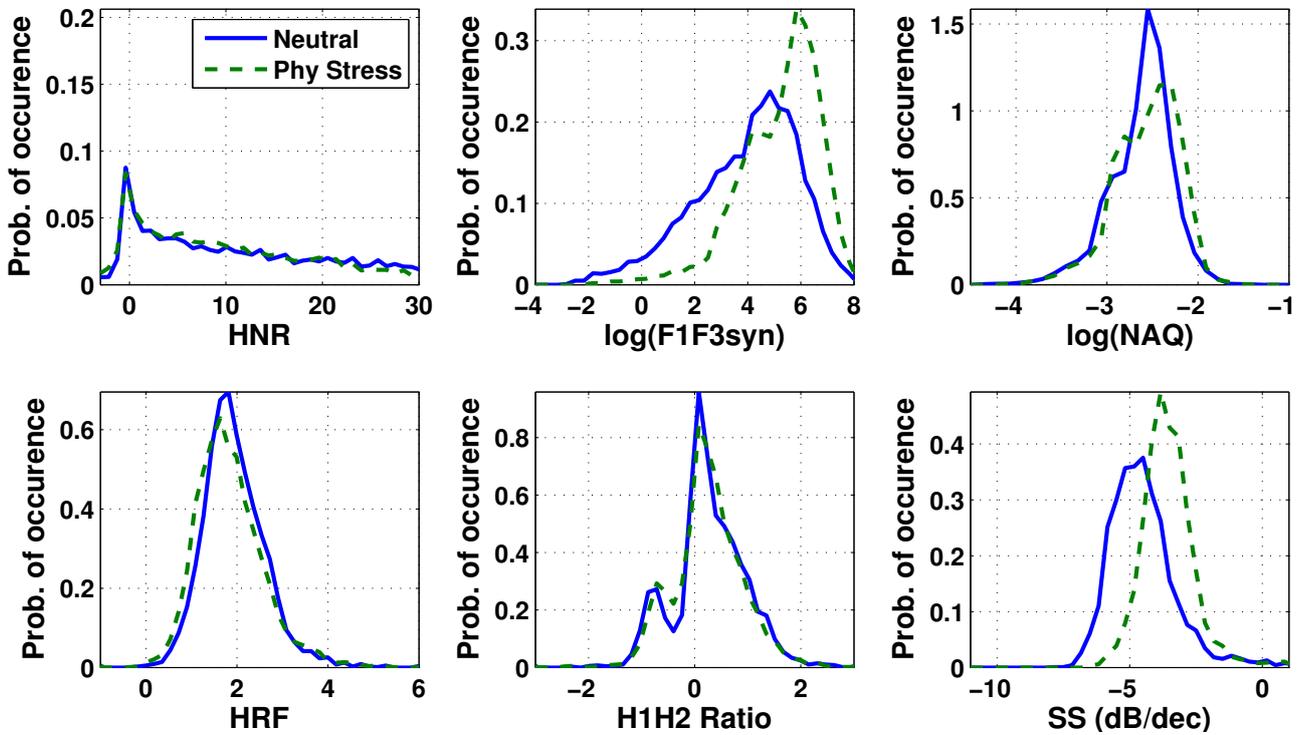

Figure 2: Parameters in physical task stress and neutral, across all voiced frames for speaker VENSF003.

all speakers, as here. These plots do not suggest that physical task stress does not affect the glottal waveshape, because Section 3 shows that these six features can be used to detect physical task stress. Instead, it appears that there are many different responses to physical task stress represented by covariation in the 6 parameters, and while they can be clustered and detected with a GMM, these separate responses average out across all recordings.

4.8. Grouping by age

To explore possible explanations for this clustering, the speakers are clustered according to age. Three groups are formed: speakers aged 18-19, speakers aged 21-30, and speakers aged 40+. In the interest of space, the plots are not shown, rather they are equivalent to the plots of Figure 1. This suggests that speaker age is not a direct explanatory factor for different vocal fold behavioral responses to physical task stress.

4.9. Grouping by exertion level

[4] showed a significant difference in a spectral measure between one of four exertion levels. Exertion level of a speaker depends on the heart rate in neutral and physical task stress, and the speaker's age. The speakers were grouped by the exertion levels from [4] and the histograms examined. They are not shown in the interest of space; they are equivalent to those of Figure 1, showing overlapping distributions. As with age, exertion level does not appear to be a direct explanatory factor for differences in vocal fold behavioral responses to physical task stress.

4.10. Individual speaker response

Finally, Figure 2 shows the six measurements averaged across all of the frames of a single speaker. The plots for F1F3syn, NAQ, and SS show apparent differences in distribution. This suggests that there are consistent vocal fold behavioral responses to physical stress at least within a single session of a single speaker's speech. It may be that speakers adopt different responses given different exertion levels or in different sessions. However, this plot does suggest some of the covariation in parameters, which may be associated with a particular behavioral response to physical stress, that make detection of physical task stress possible.

5. Conclusions

This study has shown that physical task stress detection is possible with a set of 6 glottal features. In conjunction with [1], [2], and [3], this leads to the conclusion that physical task stress affects vocal fold behavior. An analysis of the six parameters showed that across all available speech data, the distributions of the six parameters did not depend on physical task stress. Instead, given the classification result, it must be assumed that covariation in the parameters occurs in response to physical task stress. This suggests that there are behaviors that cluster in these six parameters and thus are amenable to modeling by a GMM. An analysis of age and exertion level as explanatory factors did not suggest that they directly result in clustering of vocal fold behaviors. Instead, it was shown that within a single session of a single speaker, vocal fold behavioral responses to physical task stress were consistent enough to shift the distributions of three parameters.

This consistency of response within a given session sug-

gests that if the physical task is constant, the response to stress won't necessarily vary from utterance to utterance. These results suggest future work to determine whether there are just a few overall responses to physical task stress that can be grouped together through some means of clustering the glottal parameters in this study. If so, perhaps a set of exogenous variables can be found to explain the grouping, such as speaker age, fitness level, exertion level, or fatigue level.
