

# CS 6301.002 Homework 2

Due Monday February 24th on eLearning

February 7, 2020

Please answer the following **3** questions, some of which have multiple parts.

1. **(From 3Marks/class)** Describe an  $O(n \log n)$  time algorithm that given a simple polygon  $\mathcal{P}$  with  $n$  vertices determines if  $\mathcal{P}$  is monotone with respect to some line, not necessarily a horizontal or vertical one.

*[Hint: Each reflex vertex of  $\mathcal{P}$  defines a set of allowable lines relative to which the polygon may be monotone. Can you quickly determine if there is any line appearing in all the sets?]*

2. **(From Mount)** Explain how to solve each of the following problems in linear (expected) time. Each can be modeled as a linear programming (LP) problem, perhaps with some additional pre- and/or post-processing. In each case, explain how the problem is converted into an LP instance and how the answer to the LP instance is used/interpreted to solve the stated problem. Note you *do not* need to explain how to solve the LP instance, because Kyle presented an algorithm for doing so in class.

- (a) You are given two point sets  $P = \{p_1, \dots, p_n\}$  and  $Q = \{q_1, \dots, q_m\}$  in the plane, and you are told they are separated by a vertical line  $x = x_0$ , with  $P$  to the left and  $Q$  to the right. Compute the line equations of the two “crossing tangents,” that is, the lines  $\ell_1$  and  $\ell_2$  that are both supporting lines for the convex hulls of each of  $P$  and  $Q$  such that  $P$  lies below  $\ell_1$  and above  $\ell_2$  and the reverse holds for  $Q$ . (Note that you are *not* given the hulls, just the point sets.) Your algorithm should run in  $O(n + m)$  time.

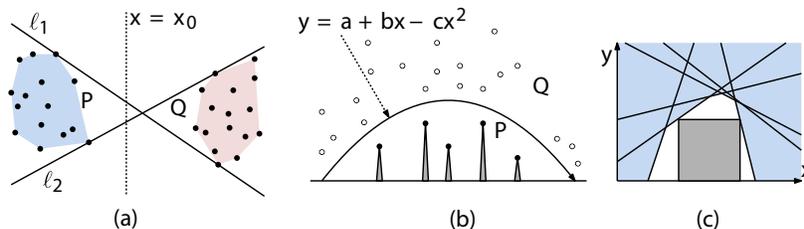

Figure 1. Examples for each of the scenarios in Problem 1.

- (b) You have a cannon in  $\mathbb{R}^2$ . It has three controls labeled “ $a$ ”, “ $b$ ”, and “ $c$ ”. A projectile shot from this cannon travels along the parabolic arc  $y = a + bx - cx^2$ . You are asked to determine whether it is possible to adjust the controls so that the projectile travels above a set of  $n$  building tops, represented by a point set  $P = \{p_1, \dots, p_n\}$  and beneath a set of  $m$  floating balloons, represented by a point set  $Q = \{q_1, \dots, q_m\}$ . Your algorithm should run in time  $O(n + m)$ . (Do not worry about the cannon’s location. Just determine if there is *some* parabola along which the projectile can travel.)
- (c) You are given a set of  $n$  halfplanes  $H = \{h_1, \dots, h_n\}$ , where  $h_i$  is given as a pair  $(a_i, b_i)$ , and it consists of all the points of the plane that lie on or beneath the line  $y = a_i x - b_i$ . Compute the axis-parallel square of the largest side length lying in  $h_1 \cap \dots \cap h_n$  whose lower edge lies on the  $x$ -axis. If no such square exists, your algorithm should indicate this.
3. **(From Mount)** The objective of this problem is to get some practice working with backwards analysis. Consider the following randomized incremental algorithm for the Pareto-set problem. Recall that the input is a set of  $n$  points  $P = \{p_1, \dots, p_n\}$  in the plane, where  $p_i = (x_i, y_i)$ , and the objective is to compute the subset of points  $p_i$  such that there is no  $p_j \in P, (j \neq i)$  such that  $x_j \geq x_i$  and  $y_j \geq y_i$ . Our approach will be to add the points one-by-one in random order. We make the usual general-position assumption that there are no duplicate  $x$ - or  $y$ -coordinates.

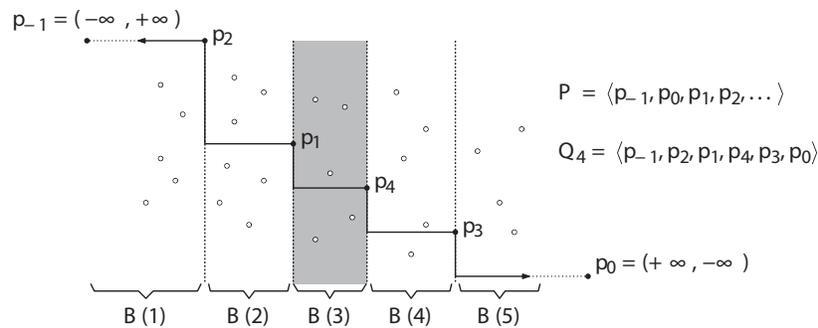

The algorithm begins by randomly permuting the point set. Let  $P = \langle p_1, \dots, p_n \rangle$  denote the permuted sequence. Let’s add two sentinel points  $p_{-1} = (-\infty, +\infty)$  and  $p_0 = (+\infty, -\infty)$ . The initial Pareto set  $Q_0$  consists of the pair  $\langle p_{-1}, p_0 \rangle$ . Observe that as we add points to the Pareto set,  $p_{-1}$  will always be the leftmost point, and  $p_0$  will always be the rightmost. For  $1 \leq i \leq n$ , let  $Q_i$  denote the sequence of points of the Pareto set after inserting  $\langle p_{-1}, \dots, p_i \rangle$ , sorted from left to right. The final output will be  $Q_n$ . Also, let  $R_i = \langle p_{i+1}, \dots, p_n \rangle$  denote the sequence of points that *remain* to be inserted.

Suppose that we have already inserted  $i - 1$  points into the Pareto set. In order to make it easy to determine where to insert the next point within the existing Pareto sequence, we will store all the remaining points of  $R_{i-1}$  in a collection of *buckets*, one for each point in the current Pareto set. Let  $Q_{i-1} = \langle p_{j_0}, p_{j_1}, \dots, p_{j_m} \rangle$ . (By our earlier observation,  $j_0 = -1$  and  $j_m = 0$ .) For  $1 \leq k \leq m$ , define  $B(k)$  to be the subset of remaining points that lie within the vertical strip between the  $(k - 1)$ st and  $k$ th points of the current Pareto sequence, that is,

$$B(k) = \{p_\ell \in R_{i-1} : x_{j_{k-1}} < x_\ell < x_{j_k}\}.$$

(For example, in the figure below, the white points in the shaded region belong to bucket  $B(3)$ , because they lie between  $x_{j_2} = x_1$  and  $x_{j_3} = x_4$ .)

- (a) Using the above structure, explain how to insert the  $i$ th point  $p_i$  and update the Pareto sequence  $Q_{i-1}$  to form  $Q_i$ . Also, explain how to update the associated buckets. (If points are removed from the Pareto sequence, then their associated bucket sets must be redistributed among the points that are currently in the Pareto sequence.) Don’t worry about detailing what data structures to use, just state which sequences/sets change and what points enter or leave them.

**Figure 2.** The example scenario for Problem 2.

- (b) Analyze the expected running time of your algorithm. Your analysis should include two elements (i) the time needed to update the Pareto sequence, and (ii) the time needed to update the associated bucket sequences. You may assume changes to the Pareto sequence or bucket sets occur in constant time per point inserted or deleted from the sequence/set. It may also help to recall the  $n$ th harmonic number  $H_n := \sum_{i=1}^n \frac{1}{i} = \Theta(\log n)$ .

[New hints: You may assume you can look up which bucket contains a given point  $p_i$  in constant time. (i) should require no appeals to randomness. For (ii), can you define the time to create a new bucket in a given iteration as a sum of indicator random variables with easily bounded expectations?]
