

# CS 7301.003.20F Lecture 10–September 21, 2020

Main topics are `#multiple-source_shortest_paths`.

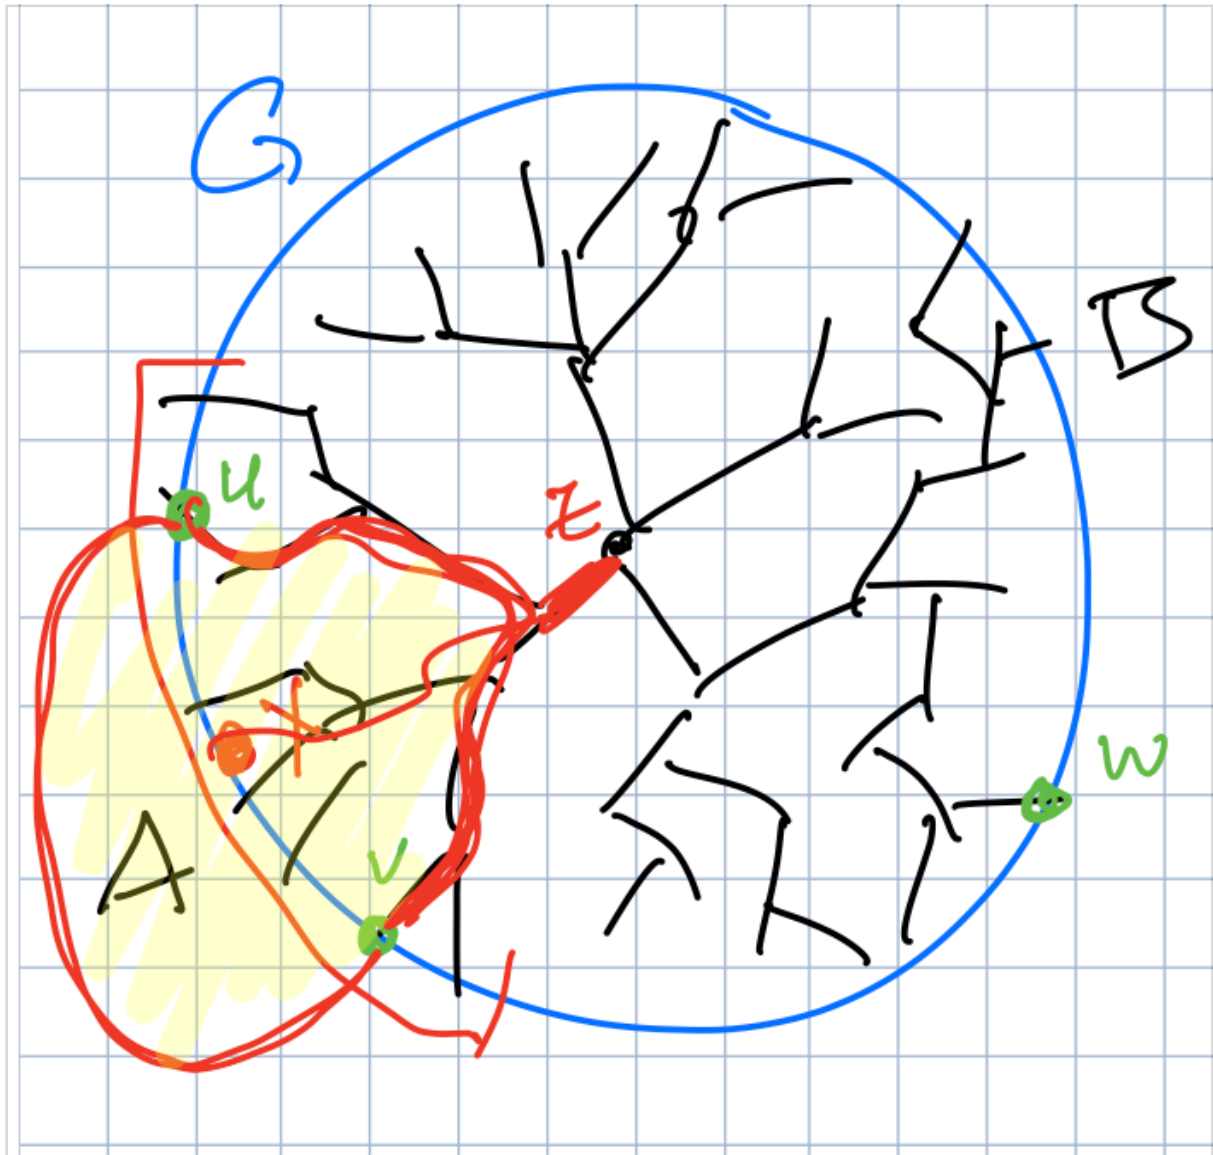

## Multiple-Source Shortest Paths

- At the end of the last lecture, I mentioned an algorithm that uses dense distance graphs (DDGs). We're given an  $r$ -division of the edges where every piece has at most  $r$  edges and  $O(\sqrt{r})$  boundary vertices lying on  $O(1)$  faces. We need to compute shortest paths within each piece between its boundary vertices, and we need to do so quickly.
- Today, we're going to look at (a modified) algorithm by Klein ['05] that computes so-called *multiple-source shortest paths*.
- Given a directed(!) plane graph  $G = (V, E)$  with outer face  $o$  and a non-negative weight function  $w : D \rightarrow \mathbb{R}^+$ , we want to compute all shortest paths rooted at every boundary vertex of  $o$ .
- If  $o$  has  $k$  vertices, then we could run Dijkstra once per vertex for  $O(kn \log n)$  time total.
- But Klein claims  $O(n \log n)$  time!
- Of course, finding all shortest paths this fast is impossible if  $k = \omega(\log n)$ . We need to be more restrictive on what we accomplish.
  - If we ask for  $p$  source-destination pairs in advance, then we can find all their distances in  $O(n \log n + p \log n)$  time.
  - Or we can build a data structure in  $O(n \log n)$  time using  $O(n \log n)$  space that answers distance queries in  $O(\log n)$  time per query.
  - Or we can find the shortest paths in  $O(1)$  time per edge if we know the paths in advance or  $O(\log \Delta)$  time per edge using the data structure if the graph has max degree  $\Delta$ .

## Trees and Disks

- Our algorithm is going to compute a shortest path tree  $T$  from some vertex on  $o$  in  $O(n \log n)$  time. Then, we're going to move the source vertex-by-vertex around  $o$ .
- Every time we move to the next vertex, some edges leave  $T$  and are replaced by other edges. The big surprise that makes the result possible is that only  $O(n)$  edges leave and enter the tree during one pass around  $o$ .
- The small number of changes is largely do to the following observation.
- Pick *any* spanning tree  $T$  of  $G$  and an edge  $e$  in  $T$ .
- $T \setminus e$  has 2 component trees. Label them  $A$  and  $B$ .
- Lemma: The set of outer face vertices in  $A$  is either empty, includes all vertices of  $o$ , or it induces a consecutive path of vertices in  $o$ .

- Suppose  $u, v$ , and  $w$  are boundary vertices such that  $u, v$  in  $A$  and  $w$  not in  $A$ .
- Let  $z$  be the least common ancestor of  $u$  and  $v$  after rooting  $T$  on an endpoint of  $e$ .
- The path from  $z$  to  $u$  along  $T$ , from  $u$  to  $v$  along a path just outside  $o$ , and from  $v$  to  $z$  along  $T$  bounds a disk.
- For any  $x$  between  $u$  and  $v$  on  $o$ , the path from  $x$  to  $e$  in  $T$  begins inside the disk and doesn't leave until hitting  $z$ . So  $x$  in  $A$ .

- Let  $s_0, s_1, \dots$  be the vertices on  $o$  and  $T_0, T_1, \dots$  be their shortest path trees.
- Pick any dart  $u \rightarrow v$ . Which trees  $T_i$  contain  $u \rightarrow v$ ?
- Let  $T_v$  be a tree of shortest paths into  $v$ .
- Assuming each  $T_i$  follows the same path  $s_i, v$ -path as in  $T_v$ , the set of  $T_i$  containing  $u \rightarrow v$  are those for which  $s_i$  lies in the  $u$  side of  $T_v \setminus uv$ .
- But we just saw those  $s_i$  are contiguous, so  $u \rightarrow v$  will enter the shortest path tree at most once and leave it at most once.
- There are  $O(n)$  darts, so the shortest path tree undergoes  $O(n)$  changes total.
- We'll assume there is exactly one shortest path between any pair of vertices so that this analysis holds. There are ways to enforce this.

## Changing Sources

- Suppose we've computed  $T := T_{i-1}$  and we want to compute  $T_i$ . There's a couple ways we could do this that all use about the same sequence of computations.
- I'm going to describe a strategy by Eisenstat and Klein [13].
- We're going to incrementally transform  $T$  into  $T_i$  using a sequence of *pivots* where one dart leaves  $T$ , and another takes its place. After all the pivots are complete, we'll have  $T_i$ .
- First, we do the *special pivot*. We remove the dart going into  $s_i$  and replace it with dart  $s_i \rightarrow s_{i-1}$ . We now have  $s_i$  as the root of  $T$ .
- Doing special pivot with no other changes means  $T$  may not be a shortest path tree. Therefore, we will temporarily assign  $s_i \rightarrow s_{i-1}$  a new weight of  $\lambda := -\text{dist}(s_{i-1}, s_i)$ .
- Define the *slack* of a dart as  $\text{slack}(u \rightarrow v) := \text{dist}(u) + w(u \rightarrow v) - \text{dist}(v)$  (where  $\text{dist}$  uses distance from the current shortest paths source vertex).
- Ford showed  $\text{slack} \geq 0$  for all edges of  $G$ , and  $\text{slack} = 0$  for all edges appearing on shortest paths. Since we're assuming shortest paths are unique, the slack is 0 if and only if the edge is in the shortest paths tree.
- Claim: Immediately after the special pivot and reweighting of  $s_i \rightarrow s_{i-1}$ ,  $T$  is a shortest path tree rooted at  $s_i$ .
  - I claim the distance to any vertex  $x$  dropped by  $\text{dist}(s_{i-1}, s_i)$  when we did the special pivot and reweighted  $s_{i-1} \rightarrow s_i$ .
  - If the new shortest path to  $x$  uses  $s_{i-1}$ , then we have prepended the old path with dart  $s_{i-1} \rightarrow s_i$ .
  - If the new shortest path doesn't use  $s_{i-1}$ , then the old path from  $s_{i-1}$  to  $s_i$  to  $x$  just had its prefix from  $s_{i-1}$  to  $s_i$  removed.
  - Other than  $s_{i-1} \rightarrow s_i$ , no weights changed, so all other slacks are the same. Finally,  $\text{slack}(s_{i-1} \rightarrow s_i) = 0$  by our choice of  $\lambda$ .
  - So  $T$  is a shortest path tree rooted at  $s_i$ , but only because  $s_i \rightarrow s_{i-1}$  has a new weight.
- We need to recover the original weight, so we'll "continuously" increase  $\lambda$ , the current weight of  $s_i \rightarrow s_{i-1}$ , until  $\lambda = w(s_i \rightarrow s_{i-1})$ , the original weight of the dart.
- What happens as we increase  $\lambda$ ?  $T \setminus (s_{i-1}, s_i)$  has two components. Those in the  $s_i$  component retain their distance from  $s_i$ . Color these vertices red. Those in the  $s_{i-1}$  component have their distances from  $s_i$  increase at the same rate  $\lambda$  is increasing. Color those blue. (Here, I'm using Klein and Mozes figures/colors. Erickson uses the opposite colors.)
- Meanwhile, what is happening to the slacks? blue  $\rightarrow$  blue and red  $\rightarrow$  red darts don't

change slack. blue  $\rightarrow$  red darts have their slack increase at the same rate  $\lambda$  is increasing.

- But red  $\rightarrow$  blue darts (except for  $s_{i-1} \rightarrow s_i$ ) have their slacks decrease at the same rate  $\lambda$  increases.

(Here,  $\text{rev}(d_i) = s_i \rightarrow s_{i-1}$ .)

- Eventually, one of the red  $\rightarrow$  blue darts  $x \rightarrow y$  hits slack 0 and is about to go negative. Let  $z \rightarrow y$  be the predecessor dart of  $y$  in  $T$ . We can now pivot  $z \rightarrow y$  out of  $T$ , replacing it with  $x \rightarrow y$ . And  $T$  is still a shortest path tree!
- $z \rightarrow y$  was blue  $\rightarrow$  blue but is now blue  $\rightarrow$  red. So its 0 slack starts to increase. We may now continue increasing  $\lambda$ .
- After a sequence of pivots,  $\lambda$  eventually reaches  $w(s_i \rightarrow s_{i-1})$  and we've computed  $T_i$ .

## Fast Pivots

- We still need a fast way to find each edge  $x \rightarrow y$  that pivots into  $T$  and perform the pivot.
- $T \setminus (s_{i-1} \rightarrow s_i)$  has red and blue components. The red-blue edges form an edge cut. In particular, they form a bond.
- The dual of this bond is a cycle.
- Let  $C := (G \setminus T)^*$  be the complementary spanning tree. The dual cycle of red-blue edges has exactly one edge outside of  $C$ , namely  $s_{i-1} \rightarrow s_i$ . The red  $\rightarrow$  blue darts with decreasing slack form a path in  $C$  from  $\text{right}(s_{i-1} \rightarrow s_i)^*$  to  $\text{left}(s_{i-1} \rightarrow s_i)^*$ . The

darts with increasing slack form the reversal of that path.

(Here, the path goes from  $f_1$  to  $f_{\infty}$ .)

- At this point, I'm going to punt and use a couple data structures as black boxes. Describing how they work would take another week.
- A *dynamic forest* data structure maintains a changing collection of darts between a fixed set of vertices. We need to guarantee that the edges always form a forest.
- We can do the following operations (and more!) in  $O(\log n)$  time per operation:
  - Link (insert) an edge between given vertices  $u$  and  $v$ .
  - Cut (delete) the edge between  $u$  and  $v$ .
  - Read or write a weight on a given vertex or dart.
  - Add a value to the weight of all darts in the unique path between given vertices  $u$  and  $v$ .
  - Add a value to the weight of all vertices in a subtree rooted at a given vertex  $u$ .
  - Find the minimum weight dart in a path.
- So, we store both  $T$  and  $C$  in separate dynamic forests. We store distances on vertices of  $T$  and slacks on darts of  $C$ . To find a normal pivot, we ask for the minimum slack  $\Delta$  on the path in  $C$ .
- To do a pivot, we decrease the slacks on the path by  $\Delta$  and increase the slacks on the reversal by  $\Delta$ . We increase distances to all blue vertices by  $\Delta$ . We do a pair of links and cuts and a pair of slack assignments to pivot the actual edges.
- So that's  $O(\log n)$  time doing a constant number of dynamic forest operations each pivot. Earlier, we saw there are  $O(n)$  pivots across the whole algorithm, so we can find all the shortest path trees in  $O(n \log n)$  time total.
- We can look up distances as we need them in  $O(\log n)$  time per distance.
- And if we use something called *persistence*, we can remember how our data structure progressed over time so we can look up shortest path distances between vertices of  $o$  and other vertices later.
