## Neural Networks

Nicholas Ruozzi

University of Texas at Dallas

## Handwritten Digit Recognition

- Given a collection of handwritten digits and their corresponding labels, we'd like to be able to correctly classify handwritten digits
- A simple algorithmic technique can solve this problem with $95 \%$ accuracy

- State-of-the-art methods can achieve near 99\% accuracy (you've probably seen these in Digits from the MNIST data set action if you've deposited a check recently)

## Neural Networks

- The basis of neural networks was developed in the 1940s 1960s
- The idea was to build mathematical models that might "compute" in the same way that neurons in the brain do
- As a result, neural networks are biologically inspired, though many of the algorithms developed for them are not biologically plausible
- Perform surprisingly well for the handwritten digit recognition task (and many others)

## Neural Networks

- Neural networks consist of a collection of artificial neurons
- There are different types of neuron models that are commonly studied
- The perceptron (one of the first studied)
- The sigmoid neuron (one of the most common, but many more)
- Rectified linear units
- A neural network is a directed graph consisting of a collection of neurons (the nodes), directed edges (each with an associated weight), and a collection of fixed binary inputs

## The Perceptron

- A perceptron is an artificial neuron that takes a collection of binary inputs and produces a binary output
- The output of the perceptron is determined by summing up the weighted inputs and thresholding the result: if the weighted sum is larger than the threshold, the output is one (and zero otherwise)

$$
y=\left\{\begin{array}{cc}
1 & w_{1} x_{1}+w_{2} x_{2}+w_{3} x_{3}>\text { threshold } \\
0 & \text { otherwise }
\end{array}\right.
$$

## Perceptrons

- Perceptrons are usually expressed in terms of a collection of input weights and a bias $b$ (which is the negative threshold)

- A single node perceptron is just a linear classifier
- This is actually where the "perceptron algorithm" comes from

## Perceptron for NOT

- Choose $w=-1$, threshold $=-.5$
- $y= \begin{cases}1 & -x>-.5 \\ 0 & -x \leq-.5\end{cases}$

## Perceptron for OR

## Perceptron for OR

- Choose $w_{1}=w_{2}=1$, threshold $=0$
- $y= \begin{cases}1 & x_{1}+x_{2}>0 \\ 0 & x_{1}+x_{2} \leq 0\end{cases}$

## Perceptron for AND

## Perceptron for AND

- Choose $w_{1}=w_{2}=1$, threshold $=1.5$
- $y= \begin{cases}1 & x_{1}+x_{2}>1.5 \\ 0 & x_{1}+x_{2} \leq 1.5\end{cases}$

## Perceptron for XOR

## Perceptron for XOR

- Need more than one perceptron!

- Weights for incoming edges are chosen as before
- Networks of perceptrons can encode any circuit!

## Neural Networks

- Gluing a bunch of perceptrons together gives us a neural network
- In general, neural nets have a collection of binary inputs and a collection of binary outputs

## Beyond Perceptrons

- Given a collection of input-output pairs, we'd like to learn the weights of the neural network so that we can correctly predict the output of an unseen input
- We could try learning via gradient descent (e.g., by minimizing the Hamming loss)
- This approach doesn't work so well: small changes in the weights can cause dramatic changes in the output
- This is a consequence of the discontinuity of sharp thresholding (same problem we saw with perceptron alg.)

## The Sigmoid Neuron

- A sigmoid neuron is an artificial neuron that takes a collection of real inputs and produces an output in the interval $[0,1]$
- The output is determined by summing up the weighted inputs plus the bias and applying the sigmoid function to the result

$$
y=\sigma\left(w_{1} x_{1}+w_{2} x_{2}+w_{3} x_{3}+b\right)
$$

where $\sigma$ is the sigmoid function

## The Sigmoid Function

- The sigmoid function is a continuous function that approximates a step function

$$
\sigma(z)=\frac{1}{1+e^{-z}}
$$

## Rectified Linear Units

- The sigmoid neuron approximates a step function as a smooth function
- The relu is given by $\max (0, x)$ which can be approximated as a smooth continuous function $\ln \left(1+e^{x}\right)$

## Softmax

- The softmax function maps a vector of real numbers to a vector of probabilities as

$$
\operatorname{softmax}(z)_{j}=\frac{e^{z_{j}}}{\sum_{k} e^{z_{k}}}
$$

- If there is a dominant value in $z$, then it will become one under the softmax
- Often used as the final layer of a neural network

## Neural Network for Digit Classification

Why 10
instead of 4?
from Neural Networks and Deep Learning by Michael Nielson

## Expressiveness of NNs

- Boolean functions
- Every Boolean function can be represented by a network with a single hidden layer consisting of possibly exponentially many hidden units
- Continuous functions
- Every bounded continuous function can be approximated up to arbitrarily small error by a network with one hidden layer
- Any function can be approximated to arbitrary accuracy with two hidden layers

## Expressiveness of NNs

- Theorem [Zhang et al. 2016]: There exists a two-layer neural network with ReLU activations and $2 n+d$ weights that can represent any function on a sample of size $n$ in $d$ dimensions
- This should mean that it is very easy to overfit with neural networks
- Generalization performance of networks is difficult to assess theoretically

## Training Neural Networks

- To do the learning, we first need to define a loss function to minimize

$$
C(w, b)=\frac{1}{2 M} \sum_{m}\left\|y^{m}-a\left(x^{m}, w, b\right)\right\|^{2}
$$

- The training data consists of input output pairs $\left(x^{1}, y^{1}\right), \ldots,\left(x^{M}, y^{M}\right)$
- $a\left(x^{m}, w, b\right)$ is the output of the neural network for the $m^{t h}$ sample
- $w$ and $b$ are the weights and biases

## Gradient of the Loss

- The derivative of the loss function is calculated as follows

$$
\frac{\partial C(w, b)}{\partial w_{k}}=\frac{1}{M} \sum_{m}\left[y^{m}-a\left(x^{m}, w, b\right)\right] \frac{\partial a\left(x^{m}, w, b\right)}{\partial w_{k}}
$$

- To compute the derivative of $a$, use the chain rule and the derivative of the sigmoid function

$$
\frac{d \sigma(z)}{d z}=\sigma(z) \cdot(1-\sigma(z))
$$

- This gets complicated quickly with lots of layers of neurons

## Stochastic Gradient Descent

- To make the training more practical, stochastic gradient descent is used instead of standard gradient descent
- Recall, the idea of stochastic gradient descent is to approximate the gradient of a sum by sampling a few indices and averaging

$$
\nabla_{x} \sum_{i=1}^{n} f_{i}(x) \approx \frac{1}{K} \sum_{k=1}^{K} \nabla_{x} f_{i^{k}}(x)
$$

here, for example, each $i^{k}$ is sampled uniformly at random from $\{1, \ldots, n\}$

## Computing the Gradient

- We'll compute the gradient for a single sample

$$
C(w, b)=\frac{1}{2}\|y-a(x, w, b)\|^{2}
$$

- Some definitions:
- $L$ is the number of layers
- $a_{j}^{l}$ is the output of the $j^{t h}$ neuron on the $l^{t h}$ layer
- $z_{j}^{l}$ is the weighted input of the $j^{\text {th }}$ neuron on the $l^{\text {th }}$ layer

$$
z_{j}^{l}=\sum_{k} w_{j k}^{l} a_{k}^{l-1}+b_{j}^{l}
$$

- $\delta_{j}^{l}$ is defined to be $\frac{\partial \mathrm{C}}{\partial z_{j}^{l}}$

## Computing the Gradient

For the output layer, we have the following partial derivative

$$
\begin{aligned}
\frac{\partial \mathrm{C}}{\partial z_{j}^{L}} & =-\left(y_{j}-a_{j}^{L}\right) \frac{\partial a_{j}^{L}}{\partial z_{j}^{L}} \\
& =-\left(y_{j}-a_{j}^{L}\right) \frac{\partial \sigma\left(z_{j}^{L}\right)}{\partial z_{j}^{L}} \\
& =-\left(y_{j}-a_{j}^{L}\right) \sigma\left(z_{j}^{L}\right)\left(1-\sigma\left(z_{j}^{L}\right)\right) \\
& =\delta_{j}^{L}
\end{aligned}
$$

- For simplicity, we will denote the vector of all such partials for each node in the $l^{\text {th }}$ layer as $\delta^{l}$

## Computing the Gradient

For the $L-1$ layer, we have the following partial derivative

$$
\begin{aligned}
\frac{\partial \mathrm{C}}{\partial z_{k}^{L-1}} & =\sum_{j}\left(a_{j}^{L}-y_{j}\right) \frac{\partial a_{j}^{L}}{\partial z_{k}^{L-1}} \\
& =\sum_{j}\left(a_{j}^{L}-y_{j}\right) \frac{\partial \sigma\left(z_{j}^{L}\right)}{\partial z_{k}^{L-1}} \\
& =\sum_{j}\left(a_{j}^{L}-y_{j}\right) \sigma\left(z_{j}^{L}\right)\left(1-\sigma\left(z_{j}^{L}\right)\right) \frac{\partial z_{j}^{L}}{\partial z_{k}^{L-1}} \\
& =\sum_{j}\left(a_{j}^{L}-y_{j}\right) \sigma\left(z_{j}^{L}\right)\left(1-\sigma\left(z_{j}^{L}\right)\right) \frac{\partial \sum_{k^{\prime}} w_{k^{\prime}}^{L} a_{k^{\prime}}^{L-1}+b_{j}^{L}}{\partial z_{k}^{L-1}} \\
& =\sum_{j}\left(a_{j}^{L}-y_{j}\right) \sigma\left(z_{j}^{L}\right)\left(1-\sigma\left(z_{j}^{L}\right)\right) \sigma\left(z_{k}^{L-1}\right)\left(1-\sigma\left(z_{k}^{L-1}\right)\right) w_{j k}^{L} \\
& =\left(\left(\delta^{L}\right)^{T} w_{* k}^{L}\right)\left(1-\sigma\left(z_{k}^{L-1}\right)\right) \sigma\left(z_{k}^{L-1}\right)
\end{aligned}
$$

## Computing the Gradient

- We can think of $w^{l}$ as a matrix
- This allows us to write

$$
\delta^{L-1}=\left(\left(\delta^{L}\right)^{T} w^{L}\right)^{T} \circ\left(1-\sigma\left(z^{L-1}\right)\right) \circ \sigma\left(z^{L-1}\right)
$$

where $\sigma\left(z^{L-1}\right)$ is the vector whose $k^{t h}$ component is $\sigma\left(z_{k}^{L-1}\right)$

- Applying the same strategy, for $l<L$

$$
\delta^{l}=\left(\left(\delta^{l+1}\right)^{T} w^{l+1}\right)^{T} \circ\left(1-\sigma\left(z^{l}\right)\right) \circ \sigma\left(z^{l}\right)
$$

## Computing the Gradient

- Now, for the partial derivatives that we care about

$$
\begin{gathered}
\frac{\partial C}{\partial b_{j}^{l}}=\frac{\partial C}{\partial z_{j}^{l}} \cdot \frac{\partial z_{j}^{l}}{\partial b_{j}^{l}}=\delta_{j}^{l} \\
\frac{\partial C}{\partial w_{j k}^{l}}=\frac{\partial C}{\partial z_{j}^{l}} \cdot \frac{\partial z_{j}^{l}}{\partial w_{j k}^{l}}=\delta_{j}^{l} a_{k}^{l-1}
\end{gathered}
$$

- We can compute these derivatives one layer at a time!

## Backpropagation

- Compute the inputs/outputs for each layer by starting at the input layer and applying the sigmoid functions
- Compute $\delta^{L}$ for the output layer

$$
\delta_{j}^{L}=-\left(y_{j}-a_{j}^{L}\right) \sigma\left(z_{j}^{L}\right)\left(1-\sigma\left(z_{j}^{L}\right)\right)
$$

- Starting from $l=L-1$ and working backwards, compute

$$
\delta^{l}=\left(\left(\delta^{l+1}\right)^{T} w^{l+1}\right)^{T} \circ \sigma\left(z^{l}\right) \circ\left(1-\sigma\left(z^{l}\right)\right)
$$

- Perform gradient descent

$$
\begin{gathered}
b_{j}^{l}=b_{j}^{l}-\gamma \cdot \delta_{j}^{l} \\
w_{j k}^{l}=w_{j k}^{l}-\gamma \cdot \delta_{j}^{l} a_{k}^{l-1}
\end{gathered}
$$

## Backpropagation

- Backpropagation converges to a local minimum (loss is not convex in the weights and biases)
- Like EM, can just run it several times with different initializations
- Training can take a very long time (even with stochastic gradient descent)
- Prediction after learning is fast
- Sometimes include a momentum term $\alpha$ in the gradient update

$$
w(t)=w(t-1)-\gamma \cdot \nabla_{w} C(t-1)+\alpha\left(-\gamma \cdot \nabla_{w} C(t-2)\right)
$$

## Overfitting

Error versus weight updates (example 1)

## Overfitting

Error versus weight updates (example 2)

## Neural Networks in Practice

- Many ways to improve weight learning in NNs
- Use a regularizer! (better generalization?)
- Try other loss functions, e.g., the cross entropy

$$
-y \log a(x, w, b)-(1-y) \log (1-a(x, w, b))
$$

- Initialize the weights of the network more cleverly
- Random initializations are likely to be far from optimal
- The learning procedure can have numerical difficulties if there are a large number of layers

## Regularized Loss

- Penalize learning large weights

$$
C^{\prime(w, b)}=\frac{1}{2 M} \sum_{m}\left\|y^{m}-a\left(x^{m}, w, b\right)\right\|^{2}+\frac{\lambda}{2}\|w\|_{2}^{2}
$$

- Can still use the backpropagation algorithm in this setting
- $\ell_{1}$ regularization can also be useful
- Regularization can help with convergence, $\lambda$ should be chosen with a validation set

## Dropout

- A heuristic bagging-style approach applied to neural networks to counteract overfitting
- Randomly remove a certain percentage of the neurons from the network and then train only on the remaining neurons
- The networks are recombined using an approximate averaging technique (keeping around too many networks and doing proper bagging can be costly in practice)

## Other Techniques

- Early stopping
- Stop the learning early in the hopes that this prevents overfitting
- Parameter tying
- Assume some of the weights in the model are the same to reduce the dimensionality of the learning problem
- Also a way to learn "simpler" models
- Can lead to significant compression in neural networks (i.e., >90\%)

## Other Ideas

- Convolutional neural networks
- Instead of the output of every neuron at layer $l$ being used as an input to every neuron at layer $l+1$, the edges between layers are chosen more locally
- Many tied weights and biases (i.e., convolution nets apply the same process to many different local chunks of neurons)
- Often combined with pooling layers (i.e., layers that, say, half the number of neurons by replacing small regions of neurons with their maximum output)
- Used extensively for image classification tasks
